Objective: To present best-practice recommendations for the prevention, recognition, and treatment of exertional heat illnesses (EHIs) and to describe the relevant physiology of thermoregulation.

Background: Certified athletic trainers recognize and treat athletes with EHIs, often in high-risk environments. Although the proper recognition and successful treatment strategies are well documented, EHIs continue to plague athletes, and exertional heat stroke remains one of the leading causes of sudden death during sport. The recommendations presented in this document provide athletic trainers and allied health providers with an integrated scientific and clinically applicable approach to the prevention, recognition, treatment of, and return-to-activity guidelines for EHIs. These recommendations are given so that proper recognition and treatment can be accomplished in order to maximize the safety and performance of athletes.

Recommendations: Athletic trainers and other allied health care professionals should use these recommendations to establish onsite emergency action plans for their venues and athletes. The primary goal of athlete safety is addressed through the appropriate prevention strategies, proper recognition tactics, and effective treatment plans for EHIs. Athletic trainers and other allied health care professionals must be properly educated and prepared to respond in an expedient manner to alleviate symptoms and minimize the morbidity and mortality associated with these illnesses.

Key Words: heat cramps, heat syncope, heat exhaustion, heat injury, heat stroke, dehydration

The prevention, recognition, and treatment of exertional heat illnesses (EHIs) are core components of sports medicine services at all levels of sport. The risk of EHI is ever present during exercise in the heat but can also occur in “normal” environmental conditions. Our current knowledge base has allowed us to greatly enhance the level of care that can be provided for athletes with these medical conditions. This document serves as the current position statement for the National Athletic Trainers’ Association (NATA) and replaces the document that was published in 2002.

The care of exertional heat-stroke (EHS) patients has come a long way in the past millennia. We now possess the knowledge to nearly assure survival from this potentially fatal injury if EHS is quickly and appropriately recognized and treated at the time of collapse. Additionally, our knowledge base and proven management protocols allow us to establish effective prevention and management strategies to minimize the risk of and improve the outcome.
from EHS, thereby affecting public health via policy creation and modification.

**DEFINITIONS OF EHIs**

**Exercise-Associated Muscle Cramps**

Exercise-associated muscle cramps (EAMCs) are sudden or sometimes progressively and noticeably evolving, involuntary, painful contractions of skeletal muscle during or after exercise. Heat cramps is a popular but technically inappropriate term for a certain category of EAMCs because they are not directly related to an elevated body temperature, do not readily occur after passive heating at rest, and can present during exercise in warm or even cool conditions and temperature-controlled conditions, although extensive sweating is typical. The signs and symptoms of incipient EAMCs can be described as tics, twinges, stiffness, tremors, or contractures, but these terms refer to conditions that are typically painless and do not demonstrate muscle activity on electromyography, unlike full-blown EAMCs. The cause of EAMCs is not fully confirmed; proposed contributing factors and conditions include dehydration, electrolyte imbalances, altered neuromuscular control, fatigue, or any combination of these factors.

**Heat Syncope**

Heat syncope, or orthostatic dizziness, often occurs in unfit or heat-unacclimatized persons who stand for a long period of time in the heat or during sudden changes in posture in the heat, especially when wearing a uniform or insulated clothing that encourages and eventually leads to maximal skin vasodilatation. This condition is often attributed to dehydration, venous pooling of blood, reduced cardiac filling, or low blood pressure with resultant cerebral ischemia. Heat syncope usually occurs during the first 5 days of unaccustomed heat exposure (eg, during the preseason), before the blood volume expands and cardiovascular adaptations are complete, and in those with heart disease or taking diuretics.

**Heat Exhaustion**

Heat exhaustion is the inability to effectively exercise in the heat, secondary to a combination of factors, including cardiovascular insufficiency, hypotension, energy depletion, and central fatigue. This condition is manifested by an elevated core body temperature (usually <40.5°C) and is often associated with a high rate or volume of skin blood flow, heavy sweating, and dehydration. It occurs most frequently in hot or humid (or both) conditions, but it can also occur in normal environmental conditions with intense physical activity. Heat exhaustion most often affects heat-unacclimatized or dehydrated individuals with a body mass index >27 kg/m². By definition, absent from heat exhaustion are end-organ damage, which would indicate heat injury (eg, renal insufficiency, rhabdomyolysis, or liver injury), and significant central nervous system (CNS) dysfunction with marked temperature elevation (>40.5°C [105°F]), which would indicate the possibility of EHS.

**Exertional Heat Injury**

Exertional heat injury is a moderate to severe heat illness characterized by organ (eg, liver, renal) and tissue (eg, gut, muscle) injury associated with sustained high body temperature resulting from strenuous exercise and environmental heat exposure. Body temperature is usually but not always greater than 40.5°C (105°F).

**Exertional Heat Stroke**

Exertional heat stroke is the most severe heat illness. It is characterized by neuropsychiatric impairment and a high core body temperature, typically >40.5°C (105°F). This condition is a product of both metabolic heat production and environmental heat load and occurs when the thermoregulatory system becomes overwhelmed due to excessive heat production (ie, metabolic heat production from the working muscles) or inhibited heat loss (ie, decreased sweating response, decreased ability to evaporate sweat) or both. Although this illness is most likely to occur in hot and humid weather, it can manifest with intense physical activity in the absence of extreme environmental conditions. The first sign of EHS is often CNS dysfunction (eg, collapse, aggressiveness, irritability, confusion, seizures, altered consciousness). A medical emergency, EHS can progress to a systemic inflammatory response and multi-organ system failure unless promptly and correctly recognized and treated. The risks of morbidity and mortality increase the longer an individual’s body temperature remains elevated above the critical threshold (>40.5°C [105°F]) and are significantly reduced if body temperature is lowered promptly.

**RECOMMENDATIONS**

The NATA advocates the following prevention, recognition, and treatment strategies for EHIs. These recommendations are presented to help certified athletic trainers and other health care providers maximize health, safety, and sport performance. However, individual responses to physiologic stimuli and environmental conditions vary widely. Therefore, these recommendations do not guarantee full protection from exertional heat-related illnesses but could mitigate the risks associated with athletic participation and physical activity. These recommendations and prevention strategies should be carefully considered and implemented by certified athletic trainers and the health care team as part of an overall strategy for the prevention and treatment of EHIs. The strength of each recommendation follows the Strength of Recommendation taxonomy (SORT; Table 1).

**Prevention**

1. Conduct a thorough, physician-supervised preparticipation medical screening before the start of the season to identify athletes with risk factors for heat illness or a history of heat illness (Table 2).

2. Individuals should be acclimatized to the heat gradually over 7 to 14 days. Heat acclimatization involves progressively increasing the intensity and duration of physical activity and phasing in protective equipment (if
applicable). If heat acclimatization is not maintained, the physiologic benefits provided by this process will decay within 3 weeks.24–26 The first 2–3 weeks of preseason practice typically present the greatest risk of EHI, particularly in equipment-intensive sports.26,27–29 All possible preventive measures should be used during this time to address this high-risk period (Figure 1). Strength of recommendation: B

3. Athletes who are currently sick with a viral infection (eg, upper respiratory tract infection or gastroenteritis) or other illness or have a fever or serious skin rash should not participate until the condition is resolved.16,27,30 Even after symptoms resolve, the athlete may still be susceptible to heat illness and should be observed carefully upon return to exercising in the heat. Strength of recommendation: B

4. Individuals should maintain euhydration and appropriately replace fluids lost through sweat during and after games and practices (see the NATA position statement on fluid replacement in athletes31). Players should have free access to readily available fluids at all times, not just during designated breaks. Instruct them to eat or drink appropriate sodium-containing fluids and foods to help replace sodium losses in sweat and urine and to enhance hydration (ie, water retention and distribution). The aims of fluid consumption or replacement are to prevent a body mass loss of more than 2% (as measured before and after the practice or game) and to keep morning urine light in color.31,32 These strategies may reduce the risk of acute and chronic significant dehydration and decrease the risk of EHI.27,31–34 Strength of recommendation: B

5. The sports medicine staff must educate relevant personnel (ie, coaches, administrators, security guards, emergency medical services [EMS] staff, athletes) on preventing and recognizing EHI and, in particular, EHS.35,36 Signs and symptoms of a medical emergency should be reviewed, and every institution should have a protocol to make an emergency action plan specific to each practice and game site. Review and rehearsal of the emergency action plan should include all relevant members of the sports medicine team (ie, coaches, athletic trainers, EMS). Strength of recommendation: C

6. Appropriate medical care must be available, and all personnel must be familiar with EHI prevention, recognition, and treatment.35–37 Certified athletic trainers and other health care providers covering practices or events are the primary providers of medical care for athletes who display signs or symptoms of EHI and have the authority to restrict an athlete from participating if EHI is suspected or to refer the athlete for a significant EHI condition. Strength of recommendation: C

7. When environmental conditions warrant, a cold-water or ice tub and ice towels should be available to immerse or soak a patient with a suspected heat illness.33,37 Immediate whole-body cooling is essential for treating EHI and EHS in particular. Onsite facilities are needed for immediate treatment. Strength of recommendation: B

8. The assessment of rectal temperature is the clinical gold standard for obtaining core body temperature of patients with EHS38 and the medical standard of practice and accepted protocol. No other field-expedient methods of obtaining core body temperature (eg, oral, axillary, tympanic, forehead sticker, temporal) are valid or reliable after intense exercise in the heat, and they may lead to inadequate or inappropriate treatment, thereby endangering a patient’s health.38–41 Parents, administrators, coaches, and student-athletes should be educated ahead of time that this procedure will be used for heat-illness emergencies, especially in patients suspected of having heat exhaustion or EHS. Esophageal and gastrointestinal

<td>Recommendation based on inconsistent or limited quality experimental evidence.</td>
</tr>
<tr>
<td>C</td>
<td>Recommendation based on consensus; usual practice; opinion; disease-oriented evidence; case series or studies of diagnosis, treatment, prevention, or screening; or extrapolations from quasi-experimental research.</td>
</tr>
</tbody>
</table>

b Patient-oriented evidence measures outcomes that matter to patients: morbidity, mortality, symptoms improvement, cost reduction, and quality of life. Disease-oriented evidence measures intermediate, physiologic, or surrogate endpoints that may or may not reflect improvements in patient outcomes (eg, blood pressure, blood chemistry, physiologic function, pathologic findings).
(via ingestible thermistor) measurements may be appropriate alternatives for temperature assessment but require advanced training for the former and careful planning for the latter. Under all circumstances in which EHS is possible, a rectal temperature assessment should be able to be obtained. Strength of recommendation: A

9. Because the effects of heat are cumulative, athletes should be encouraged to sleep at least 7 hours per night in a cool environment; eat a balanced diet; and properly hydrate before, during, and after exercise.16 Individuals should also be advised to rest in a cool environment during periods of inactivity (eg, off days, between sessions on double-practice days) to maximize recovery. Rest periods should incorporate meal times and allow 2 to 3 hours for food, fluids, electrolytes (primarily sodium and chloride), and other nutrients to be digested and absorbed before the next practice or competition. Strength of recommendation: C

10. To anticipate potential problems, a preseason heat-acclimatization policy should be developed for organized sports and event guidelines formulated for hot, humid weather conditions based on the type of activity and wet-bulb globe temperature (WBGT).23,26 In stressful environmental conditions, particularly during the first 2–3 weeks of preseason practice, activity should be delayed or rescheduled or the practice session shortened to reduce the risk to participants. Special attention should be given to practice drills that involve high-intensity activity and full protective equipment worn by players, as these factors may exacerbate the amount of heat stress on the body. Strength of recommendation: B

11. Individuals who may be particularly susceptible to EHI must be identified.42–45 They should be closely monitored during stressful environmental conditions, and preventive steps should be taken.45,46 In addition, emergency supplies and equipment (eg, tubs for cold-water immersion [CWI], rectal thermometer) should be onsite, easily accessible, and in good working order to allow for immediate intervention and treatment if needed. Strength of recommendation: B

12. Rest breaks should be planned and the work-to-rest ratio modified to match the environmental conditions and the intensity of the activity.45–47 Breaks should be in the shade or in a predetermined cooling zone and should allow enough time for all athletes to consume fluids. Additionally, players should be permitted to remove equipment (eg, helmets) during rest periods. Strength of recommendation: B

13. The use of dietary supplements and other substances that have a dehydrating effect, increase metabolism, or affect body temperature and thermoregulation is discouraged.48 Because supplements may increase the risk of EHI, their use should be carefully monitored. Strength of recommendation: C

14. Minimal experimental evidence exists regarding the most effective method of preventing EAMCs due to the variety of causes. Supplemental sodium ingestion and fluid monitoring9 or neuromuscular reeducation49 may help to prevent EAMC recurrences. Clinicians should identify the patient’s unique intrinsic (eg, hydration, acclimatization, biomechanics, training status) and extrinsic (eg, climate conditions, exercise intensity) risk factors that preceded EAMCs before implementing a prevention strategy. Strength of recommendation: C

Recognition

Exercise-Associated Muscle Cramps.

15. A patient experiencing EAMCs will likely show 1 or more of the following signs and symptoms: visible cramping in part or all of the muscle or muscle groups, localized pain, dehydration, thirst, sweating, or fatigue.4,5,50 Strength of recommendation: C

16. A thorough medical history should be obtained to distinguish muscle cramping as a result of an underlying clinical condition (eg, sickle cell trait) from EAMCs.50 The latter is often preceded by subtle muscle twitching, whereas the former is not. Strength of recommendation: C

17. Most EAMCs related to overload or fatigue tend to be short in duration (less than 5 minutes) and mild in
However, some EAMCs severely affect athletic performance and as a result, prohibit further exercise; require further medical attention to resolve; or elicit soreness for several days.\(^7,49-51\) \textit{Strength of recommendation: B}

**Heat Syncope.**

18. A patient who experiences a brief episode of fainting associated with dizziness, tunnel vision, pale or sweaty skin, and a decreased pulse rate while standing in the heat or after vigorous exercise (with a relatively low rectal temperature [\(<39^\circ\text{C}\)] is likely experiencing heat syncope.\(^12\) However, responsiveness, breathing, and pulse must be assessed to rule out a cardiac event, which can present with similar signs and symptoms but is a more serious condition. \textit{Strength of recommendation: B}

19. A thorough medical history and physical examination should be performed to eliminate any other medical conditions that could cause syncope. \textit{Strength of recommendation: C}

**Exertional Heat Exhaustion.**

20. Heat exhaustion may be present if the patient demonstrates excessive fatigue, faints, or collapses with minor cognitive changes (eg, headache, dizziness, confusion) while performing physical activity.\(^15\) yet the athletic trainer should assess the patient’s CNS function by noting any bizarre behavior, hallucinations, altered mental status, confusion, disorientation, or coma that may indicate a more serious condition such as EHS. Other signs and symptoms of exertional heat exhaustion may include fatigue, weakness, dizziness, headache, vomiting, nausea, lightheadedness, low blood pressure, and impaired muscle coordination. \textit{Strength of recommendation: B}

21. It is strongly recommended that a rectal temperature be obtained to differentiate exertional heat exhaustion from the more serious EHS. With heat exhaustion, core body temperature (measured rectally) is usually less than 40.5^\circ\text{C} (105^\circ\text{F}), a key characteristic that differentiates it from EHS. \textit{Strength of recommendation: A}

**Exertional Heat Stroke.**

22. The 2 main diagnostic criteria for EHS are CNS dysfunction and a core body temperature greater than 40.5^\circ\text{C} (105^\circ\text{F}).\(^16,19,52\) However, if a suspected EHS victim exhibits CNS dysfunction even though the rectal temperature is slightly lower (ie, 40^\circ\text{C} [104^\circ\text{F}]), it is prudent to assume the patient is suffering from EHS and begin the appropriate treatment. After initial collapse, recognition is often delayed, and the patient may begin to cool passively, dropping below the 40.5^\circ\text{C} (105^\circ\text{F}) threshold. Rectal temperature thermometry is the only method of obtaining an immediate and accurate measurement of core body temperature. Other devices, such as oral, axillary, aural canal, tympanic, forehead sticker, and temporal artery thermometers, inaccurately assess the body temperature of an exercising person.\(^38-41\) A delay in accurately assessing temperature during diagnosis may also explain a body temperature that is lower than expected. \textit{Strength of recommendation: A}

23. Because immediate treatment is vital in EHS, it is important to not waste time by substituting an invalid method of temperature assessment if rectal thermometry is not available. Instead, the practitioner should rely on other key diagnostic indicators (ie, CNS dysfunction, circumstances of the collapse). If EHS is suspected, CWI (or another rapid cooling mechanism if CWI is not available) should be initiated immediately. \textit{Strength of recommendation: C}

24. In a patient suspected of having EHS, CNS function should be assessed. Signs and symptoms can include disorientation, confusion, dizziness, loss of balance, staggering, irritability, irrational or unusual behavior, apathy, aggressiveness, hysteria, delirium, collapse, loss of consciousness, and coma. In some cases, a lucid interval may be present; however, if EHS is present, the patient will likely deteriorate quickly. \textit{Strength of recommendation: B}

25. Other signs and symptoms of EHS that may be present include dehydration, hot and wet skin, hypotension, and hyperventilation. Most patients with EHS have hot, sweaty skin as opposed to those with the classical type of heat stroke (the passive condition that typically affects children and the elderly), who present with dry skin. \textit{(Table 3). \textit{Strength of recommendation: B}}

**Heat Injury.**

26. Heat injury is a moderate to severe heat illness characterized by end-organ damage but the absence of the profound CNS dysfunction often found with EHS.\(^17,18\) Evaluation usually reveals very dark (cola-colored) urine, severe muscle pain, and abnormal blood chemistry levels. \textit{Strength of recommendation: B}

**Treatment**

**Exercise-Associated Muscle Cramps.**

27. The immediate treatment for acute EAMCs related to muscle overload or fatigue is rest and passive static stretching of the affected muscle until cramps abate.\(^7,51,53\) Icing, massage, or both may also help relieve some of the discomfort after EAMCs.\(^5\) For EAMCs related to excessive sweating and a suspected whole-body sodium deficit, the patient must ingest sodium-containing fluids (preferably) or foods (or both) to help return the body to normal fluid, electrolyte, and energy distribution. \textit{Strength of recommendation: B}

28. Fluid absorption, retention, and distribution are enhanced by beverages that contain sodium and carbohydrates. A high-sodium product (eg, salt packet) may be added to a beverage to help offset sodium lost via exercise-induced sweating. Similarly, small volumes (eg, 1 mL per 1 kg body weight) of a salty solution such as pickle juice may be consumed, if tolerated, without negatively affecting ad libitum water ingestion,\(^54\) plasma electrolyte concentrations,\(^55\) or thirst or causing nausea or stomach fullness.\(^54\) \textit{Strength of recommendation: B}

29. Patients with EAMCs are normally conscious and responsive and have normal vital signs.\(^50\) Thus, clinicians can provide fluids orally to a patient suffering from EAMCs who is compliant and tolerating fluid intake. The use of intravenous fluids should be considered if the patient is noncompliant or unable to tolerate fluids.\(^5\) \textit{Strength of recommendation: A}

30. Patients with recurring EAMCs should undergo a thorough medical screening to rule out more serious
neuromuscular conditions (eg, fatigue, hydration level, improper nutrition).\textsuperscript{50} \textit{Strength of recommendation: C}

**Heat Syncope.**

31. The clinician should move the patient to a shaded area, monitor vital signs, elevate the legs above the level of the heart, cool the skin, and rehydrate.\textsuperscript{12} \textit{Strength of recommendation: C}

**Exertional Heat Exhaustion.**

32. Removing any excess clothing and equipment increases the evaporative surface of the skin and facilitates cooling. \textit{Strength of recommendation: C}

33. The patient should be moved to a cool or shaded area. Further body cooling should be accomplished via fans or ice towels if necessary. \textit{Strength of recommendation: C}

34. While monitoring vital signs, the clinician should place the patient in the supine position with legs elevated above the level of the heart to promote venous return.\textsuperscript{15,16,56} \textit{Strength of recommendation: C}

35. If intravenous fluids are needed or if recovery is not rapid (within 30 minutes of initiation of treatment) and uneventful, fluid replacement should begin and the patient’s care transferred to a physician. If the condition worsens during or after treatment, EMS should be activated.\textsuperscript{15,16,56} Additionally, rectal temperature should be obtained; if \( >40.5 \text{ºC} \) (\( 105 \text{ºF} \)), the patient should be treated for EHS. \textit{Strength of recommendation: C}

**Exertional Heat Stroke.**

36. For any EHS patient, the goal is to lower core body temperature to less than 38.9 \textdegree C (102 \textdegree F) within 30 minutes of collapse.\textsuperscript{20} Body cooling serves 2 purposes: returning blood flow from the skin to the heart and lowering core body temperature by reducing the hypermetabolic state of the organs. The length of time the core body (and particularly the brain) is above the critical temperature threshold (40.5 \textdegree C [105 \textdegree F]) dictates morbidity and the risk of death from EHS (Figure 2).\textsuperscript{57,58} \textit{Strength of recommendation: B}

37. When EHS is suspected, the patient’s body (trunk and extremities) should be quickly immersed in a pool or tub of cold water. Removing excess clothing and equipment will enhance cooling by maximizing the surface area of the skin. However, because removing excess clothing and equipment can be time consuming, CWI should begin immediately and equipment should be removed while the patient is in the tub (or while temperature is being assessed or the tub is being prepared).\textsuperscript{59} Rectal temperature and other vital signs should be monitored during cooling every 5 to 10 minutes if a continuous monitoring device is not available.\textsuperscript{20,60} \textit{Strength of recommendation: B}

38. Cold-water immersion up to the neck is the most effective cooling modality for patients with EHS.\textsuperscript{57} The water should be approximately 1.7 \textdegree C (35 \textdegree F) to 15 \textdegree C (59 \textdegree F) and stirred continuously to maximize cooling. The patient should be removed when core body temperature reaches 38.9 \textdegree C (102 \textdegree F) to prevent overcooling (Table 4).\textsuperscript{56} \textit{Strength of recommendation: A}

39. Although cooling rates may vary, the cooling rate for CWI will be approximately 0.2 \textdegree C/min (0.37 \textdegree F/min) or about 1 \textdegree C every 5 minutes (or 1 \textdegree F every 3 minutes) when considering the entire immersion period from postcollapse to 38.9 \textdegree C (102 \textdegree F).\textsuperscript{20,57,58} \textit{Strength of recommendation: B}

40. If full-body CWI is not available, partial-body immersion (ie, torso) with a small pool or tub and other modalities, such as wet ice towels rotated and placed over the entire body or cold-water dousing with or without fanning, may be used but are not as effective as CWI.\textsuperscript{61,62} \textit{Strength of recommendation: B}

41. If a physician is onsite (as in a mass medical tent situation) and can manage the EHS, then transportation to a medical facility may not be necessary if cooling occurred immediately (ie, if the duration above 40 \textdegree C [104 \textdegree F] was less than 30 minutes) and the patient is asymptomatic 1 hour postcooling. If a physician is not present but other medical staff (eg, AT, EMS, nurse) are onsite, aggressive cooling should continue until the patient’s temperature is 39 \textdegree C (102.8 \textdegree F). When medical staff is onsite, all patients with EHS should be cooled first and transported second. However, when medical staff is not present and EHS is suspected, then the coaching

---

**Notes:**

1. AT = athletic trainer.
2. EMS = emergency medical services.

---
staff/supervisors should implement cooling until medical assistance arrives. **Strength of recommendation: B**

42. Policies and procedures for cooling patients before transport to the hospital must be explicitly stated in an emergency action plan and shared with potential EMS responders so that treatment of EHS by all medical professionals is coordinated (Figure 3). **Strength of recommendation: B**

### Return to Activity

43. In cases of EAMCs or heat syncope, the athletic trainer should monitor the patient’s condition until signs and symptoms are no longer present. **Strength of recommendation: C**

44. In patients with heat exhaustion, same-day return to activity is not recommended and should be avoided.**56**

45. Many patients with EHS are cooled effectively and sent home the same day; they may be able to resume modified activity within 1 month with a physician’s clearance. However, when treatment is delayed (ie, not provided within 30 minutes), patients may experience residual complications for months or years after the event. **Strength of recommendation: C**

46. Most guidelines suggest that a patient recovering from EHS be asymptomatic with normal blood-work results (renal and hepatic panels, electrolytes, and muscle enzyme levels) before a gradual return to activity is initiated.**49** Unfortunately, few evidence-based strategies have been developed to determine recovery of the thermoregulatory system, so the medical professional must use clinical cues such as ongoing signs and symptoms, responses to a standard exercise heat-tolerance test, responses to gradually increasing exercise demands, and ability to acclimatize to the heat to make return-to-play decisions. **Strength of recommendation: C**

47. In all cases of EHS, after the patient has completed a 7- to 21-day rest period, demonstrated normal blood-work results, and obtained physician clearance, he or she may begin a progression of physical activity, supervised by the athletic trainer or other medical professional with knowledge of EHS treatment and care, from low intensity...
to high intensity and increasing duration in a temperate environment, with equipment added gradually where indicated. Also, a graded progression of heat acclimatization, while monitoring for signs and symptoms of EHI, should be completed. The ability to progress depends largely on the treatment provided, and in some rare cases, full recovery may not be possible. Rectal temperature and heart rate should be monitored during these activities, and if the patient experiences any side effects or negative symptoms with training, the progression should be slowed, delayed, or stopped.  

**Strength of recommendation:** C

48. Although structured guidelines for return to play after EHS in athletics are lacking, the US military has adopted effective recommendations for the proper progression of return to duty after an episode of EHS. The main considerations are treating any associated sequelae and, if possible, identifying the cause of EHS, so that future episodes can be prevented. As evidence-based medicine research has advanced, the role of exercise heat-tolerance testing has gained favor as a commonsense approach: a patient who has a poor test result should not increase activity at that point. However, the significance of a normal test result and its relationship with clearance to return to play still need to be refined and evaluated. In either circumstance, monitoring the physiologic response to series of challenging exercise heat exposures is a large step forward in our delivery of health care to the EHS patient who is recovering and working toward a return to physical activity as a laborer, soldier, or athlete. This method has proved effective within the Israeli military, and the US military and at the Korey Stringer Institute, and it supports many of the considerations put forth by the American College of Sports Medicine and US military. 

**Strength of recommendation:** C

**BACKGROUND AND REVIEW OF THE LITERATURE**

**Thermoregulation**

Thermoregulation is a complex interaction of the CNS, the cardiovascular system, and the skin to maintain a core body temperature of approximately 37°C (98.6°F). 

The CNS temperature-regulation center, located in the
hypothalamus, is where the core temperature setpoint is determined. The hypothalamus receives information regarding core body temperature and skin temperature from peripheral skin receptors and the circulating blood. This interaction regulates core body temperature via an open-ended feedback loop similar to a home thermostat system. Based on the peripheral feedback sent to the hypothalamus, the body adjusts accordingly to initiate the appropriate heat-transfer responses. If core temperature falls below the normal setpoint, peripheral vasoconstriction and shivering responses increase core body temperature, whereas if core temperature rises above the normal setpoint, cutaneous vasodilation and increased sweating occur to dissipate heat.70,71

Core body temperature is determined by metabolic heat production and the transfer of body heat to and from the surrounding environment by the following heat-balance equation71:

\[
S = M(\pm \text{work}) - E \pm R \pm C \pm K,
\]

where \(S\) is the amount of stored heat, \(M\) is the metabolic heat production, \(E\) is the evaporative heat loss, \(R\) is the heat gained or lost by radiation, \(C\) is the heat lost or gained by convection, and \(K\) is the heat lost or gained by conduction. Basal metabolic heat production while fasting and at absolute rest is approximately 60 to 70 kcal/h for an average adult, with 50% of the heat being produced by internal organs.72 Metabolic heat produced by intense exercise may approach 1000 kcal/h, with more than 90% of the heat resulting from metabolism in muscles.72 Heat is further gained or lost by 1 or more of the following mechanisms.72

Radiation: Heat is transferred to or from an object or body via electromagnetic radiation (ie, sunlight) from higher to lower energy surfaces.

Conduction: Heat is transferred from warmer to cooler objects through direct physical contact (eg, ice packs).

Convection: Heat is transferred to or from the body to surrounding fluid or air (eg, moving air from a fan or immersion in water).

Evaporation: Heat is transferred via the vaporization of sweat. This is the most efficient means of heat transfer. The evaporation of sweat from the skin depends on the water saturation of the air (ie, humidity level) and the velocity of the moving air (ie, wind speed).17,30,70–73 The effectiveness of evaporation for heat loss from the body diminishes rapidly when the humidity level is high.

**Exercise-Associated Muscle Cramps**

The most common EHI experienced by athletes is EAMCs.74 They afflict adolescents, adult athletes,7,51,75 soldiers, and industrial workers. They are seemingly unpredictable, though affected athletes often report muscle twinges before they experience full-blown, debilitating muscle cramping. Probably because spinal inhibition is weakest when a muscle contracts forcefully while shortened, EAMCs usually occur when muscles are in this position.76 Although they may occur in any muscle, EAMCs related to muscle overload or fatigue tend to affect exercising (or constantly loaded) muscles, especially those that cross 2 joints in the lower extremities (eg, gastrocnemius, hamstrings).7 Patients experiencing EAMCs typically display a transient inability to continue normal activity and may have muscle soreness for days postcramping.50

Their cause is controversial,4,10 but a growing body of experimental,76–79 quasieperimental,6–8,51,75 and case49 studies suggest that EAMCs are not the result of dehydration or electrolyte losses. Although athletes prone to EAMCs may have substantial fluid (2 to 3.4 L/h) and sodium (up to 5 g or far more in a single session) losses,9,11 the volume of fluid ingested,11 postexercise body weights,7,8,11 and gross sweat losses11 are often comparable with those of noncramping athletes. These findings underscore that such measures (or blood sodium concentration) do not necessarily indicate a whole-body sodium deficit. Potential risk factors for EAMCs consistent across several prospective cohort studies7,51,75,80 include a history of EAMCs; faster competition performance times; and prior muscle, tendon, or ligament injury. In contrast, stretching history, muscle flexibility, training frequency or volume, height, age, body mass index, weight, and sex tend not to be adequate predictors of EAMC occurrence.7,51,75,80

The most effective treatment for acute EAMCs is static stretching of the affected muscle until the cramp subsides.7,51,53 Stretching reduces the activity of cramping muscles53 and may relieve cramps by increasing the inhibition produced by the Golgi tendon organs4,76 or the physical separation of contractile proteins (or both).53 The effectiveness of chronic or acute static stretching as prophylaxis against future EAMC episodes is unknown. Those patients with EAMCs related to a whole-body sodium deficit must be promptly treated with a high-salt solution, either orally or intravenously. However, it is important to note that this treatment will not result in immediate relief of muscle cramping because of the time necessary to properly absorb sodium.

No well-designed, controlled cohort or experimental studies have compared the effectiveness of EAMC prophylactics, yet some case studies suggest that fluid and electrolyte monitoring and replacement7 or neuromuscular reeducation49 may effectively reduce EAMC recurrence.

**Hyperthermia and EHS**

Signs and symptoms of hyperthermia include dizziness, confusion, behavioral changes, coordination difficulties, decreased cognitive function, reduced physical performance, and collapse.15,52,69,71,72,81,82 The residual effects of elevated core body temperature depend on the duration, not necessarily the degree, of the hyperthermia.46,57,69,82 Moderate exercise-induced hyperthermia is normal and even protective in that it triggers the body’s thermoregulatory system. However, with EHS (core body temperature greater than 40.5°C [105°F]), long-term neurologic deficits are possible if the condition is not quickly recognized and treated. When EHS is immediately treated via rapid whole-body cooling and core body temperature is normalized within 30 minutes of collapse, a 100% survival rate with limited or no sequelae has been reported.57,69

The fastest way to decrease core body temperature is full-body CWI in a pool or tub (with a water temperature between 1°C [35°F] and 15°C [59°F]).57,61,69 Timely (less than 30 minutes from the time of collapse) CWI therapy was associated with a 0% fatality rate in more than 2000

</tbody>
</table>

**Guidelines for hydration and rest breaks**
1. Rest time should involve both unlimited hydration intake (water or electrolyte drinks) and rest without any activity involved.
2. For football, helmets should be removed during rest time.
3. The site of the rest time should be a “cooling zone” and not in direct sunlight.
4. When the WBGT reading is greater than 86°F (30°C):
   a. Ice towels and spray bottles filled with ice water should be available at the “cooling zone” to aid the cooling process.
   b. Cold-immersion tubs must be available for practices for the benefit of any player showing early signs of heat illness.

**Definitions**
1. **Practice:** The period of time that a participant engages in a coach-supervised, school-approved sport or conditioning-related activity.
2. **Walk-through:** This period of time shall last no more than 1 h, is not considered to be a part of the practice-time regulation, and may not depend entirely on evaporation. 17,30,71,72 Yet when the environmental temperature is higher than the body’s skin temperature, individuals can more readily predispose an EHS.* When the environmental conditions, (2) intensity of activity, (3) heat-acclimatization status, (4) equipment and clothing, (5) fitness of individual, and (6) age of participants.

---

EHS patients in athletics and military settings. Other forms of cooling (eg, cold-water dousing with fans, ice-water towels) may be used if CWI is not available, but these methods decrease core body temperature at a slower rate than does CWI.61,62,69

**Environmental Risk Factors**

**Environmental Conditions.** Hot and humid environmental conditions can more readily predispose an individual to EHS.* When the environmental temperature is higher than the body’s skin temperature, individuals absorb heat from the environment, and their heat loss depends entirely on evaporation.17,30,71,72 Yet when humidity is also high, evaporative heat loss is severely diminished, which can lead to a rapid rise in core body temperature and an extreme risk for EHS (Table 5).

The environmental factors that influence the risk of heat illness include the ambient temperature, relative humidity (amount of water vapor in the air), air motion (wind speed), and amount of radiant heat from the sun. The relative risk of heat illness can be calculated using the WBGT equation:

\[
\text{WBGT} = (\text{wet-bulb temperature} \times 0.7) + (\text{black-globe temperature} \times 0.2) + (\text{dry-bulb temperature} \times 0.1).
\]

This equation is used to estimate the risk associated with exercise based on environmental conditions and can be useful for setting local policies regarding environmental heat. The WBGT index has long been used in athletics and by the US military. Using the WBGT index to modify activity in high-risk settings has greatly diminished the occurrence of EHS cases in US Marine Corps recruits. However, due to geographical differences among athletic teams and schools across the United States, the WBGT index may not be the most appropriate tool in determining a universal policy for activity modifications and cancellations.84 Therefore, caution is necessary when setting protocols based solely on climate due to differences among the various regions of the country. It should be noted that an EHI could occur in seemingly “normal” environmental conditions and, therefore, all appropriate precautions should be taken, especially in the first week of practice (Table 6).

**Barriers to Evaporative Heat Loss.** Athletic equipment and rubber or plastic suits used for weight loss do not allow water vapor to pass from the skin to the environment and, as a result, inhibit evaporative, convective, and radiant heat loss.27,42,86,87 Participants who wear equipment that does not allow for heat dissipation are at an increased risk for heat illness. Wearing a helmet is also a risk factor because a significant amount of heat is dissipated through the head. Individuals are most susceptible to EHI during the first week of preseason practices.29,88,89 Thus, it is important to include a phase-in of equipment as part of the heat-acclimatization period.

**Wet-Bulb Globe Temperature the Previous Day and Night.** When individuals compete in high WBGT conditions, the risk of EHI increases the following day.91 This factor appears to be one of the best predictors of EHI and should be considered when planning successive practice sessions. Additionally, individuals who sleep in warm or non–air-conditioned quarters are also at greater risk due to the cumulative effects of heat exposure.

**Excessive Clothing or Equipment.** Excessive clothing or equipment decreases the body’s ability to thermoregulate and may cause greater absorption of radiant heat from the environment.

Nonenvironmental Risk Factors

Heat Acclimatization. Heat acclimatization is a physiologic response to repeated heat exposure during exercise over the course of 10 to 14 days. This response enables the body to cope more effectively with thermal stressors and consists of increases in stroke volume and sweat rate and decreases in heart rate, core body temperature, skin temperature, sweat rate, and decreases in heart rate, core body temperature, skin temperature, and sweat salt losses. Individual differences affect the onset and decay of heat acclimatization. The rate of acclimatization is related to aerobic conditioning and fitness; in general, a better conditioned athlete will acclimatize to the heat more quickly.

Exercise Intensity. The rate of metabolic heat production is clearly a function of the intensity of physical exertion. The relative intensity of exercise, which is based in part on individual physical fitness, has the greatest influence on the rate of increase in core body temperature. From a physiologic standpoint, high-intensity exercise results in a substantial amount of metabolic heat production, which then produces a rapid rise in core body temperature. This rapid rise in temperature often exceeds the ability of the body to dissipate heat, ultimately overwhelming the thermoregulatory system. From a behavioral standpoint, individuals will often use an anticipatory defense mechanism and behavioral modifications (e.g., slowing their pace) to protect themselves against dangerous levels of hyperthermia. However, during competition, the will to win or to accomplish a personal best may trump this internal cue. In addition, external pressure from coaches or teammates may force athletes to ignore this protective instinct.

Overzealousness. Overzealous athletes are at higher risk for EHI because they tend to override the normal behavioral adaptations to heat and ignore early warning signs of EHI.

Poor Physical Condition. Untrained individuals are more susceptible to EHI than trained individuals because, as aerobic power (VO2max) improves, the ability to withstand heat stress generally also improves. High-intensity exercise can readily produce 1000 kcal/h and elevate the core temperature of at-risk athletes (those who are unfit, overweight, or unacclimatized) to a dangerous level in less than 30 minutes.

Increased Body Mass Index. Obese people are at increased risk for EHI because they are less efficient in dissipating heat and produce more metabolic heat during exercise. Conversely, those who are muscle bound produce increased metabolic heat and have a lower ratio of surface area to mass, contributing to a decreased ability to dissipate heat.

Dehydration. Excess sweat loss, inadequate fluid intake, vomiting, diarrhea, certain medications, and alcohol can lead to a measureable fluid deficit. Proper hydration can help to reduce exercise heart rate, fatigue, and core body temperature. While increasing performance and cognitive functioning, dehydration of as little as 2% of body weight can negatively affect performance and thermoregulation. Caution should be taken to ensure that athletes arrive at practice euhydrated (i.e., having reestablished their weight since the last practice) and replace body water that is lost during practice. Measuring body-weight change before, during, and after a practice or an event and across successive days is the preferred method for monitoring dehydration in the field. Using a clinical refractometer is another effective method of estimating hydration status: specific gravity should be no more than 1.020 at the start of the activity and no more than 1.024 at the end of the activity. Hydration status can also be identified by monitoring the first-void morning urine color via a urine color chart (urine color should be no more than 4).

Water loss that is not sufficiently regained by the next practice increases the risk for EHI. Cumulative dehydration develops insidiously over several days and is typically observed during the first few days of preseason practices and in tournament competition. Cumulative dehydration can be detected by monitoring daily prepractice and postpractice body weights and morning urine color. During intense exercise in the heat, sweat rates can be as high as 2 L/h; if the fluid is not replaced, large deficits will result. Therefore, the rehydration rate may have to be increased during exercise periods of this nature in order to minimize fluid deficits.

Illness. Individuals who are currently or were recently ill may be at increased risk for EHI because of fever, dehydration, or medications (e.g., decongestants or antidiarrheal agents).

History of Exertional Heat Illness. Athletes with a history of heat illness are often at greater risk for recurrent heat illness during strenuous physical activity due to the potential for widespread debilitation involving the thermoregulatory, central nervous, cardiovascular,
musculoskeletal, renal, and hepatic systems.\textsuperscript{20,33,42,65–68} However, these long-term effects are markedly reduced if proper treatment is initiated within 10 minutes of collapse.\textsuperscript{57} Identifying the cause of the heat illness and making appropriate decisions to correct the cause will decrease the risk of subsequent heat illnesses.\textsuperscript{66} Therefore, the clinician’s thorough understanding of the common causes and predisposing factors of EHI is extremely important. Addressing these common causes and implementing proper strategies to mitigate their harmful effects may be the most important approach in avoiding EHIs.

**Medications and Drugs.** Individuals who take certain medications or drugs, particularly those with a dehydrating effect or those that increase metabolic rate, are at increased risk for EHI.\textsuperscript{113–116} Medications that have been suggested to have an adverse effect on thermoregulation include stimulants, antihistamines, anticholinergics, and antipsychotics.\textsuperscript{116} Approximately one-third of high school football players reportedly used dietary supplements, most for the purpose of increasing muscle mass.\textsuperscript{113} Although such substances do not preclude participation, clinicians should recognize that these athletes are at higher risk and ensure adherence to acclimatization and hydration strategies and observe and intervene to protect if the athlete appears to be struggling.

**Electrolyte Imbalance.** Electrolyte imbalances can occur even in trained, acclimatized individuals who engage in regular physical activity and eat a normal diet. Most sodium and chloride losses occur through the urine, but people with high sweat rates (eg, >2 L/h) and sodium concentrations and those who are not heat acclimatized can lose significant amounts of sodium during physical activity. It is important to emphasize that athletes’ meals should replace electrolyte losses and thereby allow them to avoid salt-depletion dehydration. Electrolyte imbalances also commonly arise with the use of diuretics.\textsuperscript{117,118}

**Hospitalization and Recovery**

After an episode of EHS, the patient may experience impaired thermoregulation, persistent CNS dysfunction, hepatic insufficiency, and renal insufficiency.\textsuperscript{65–67,119} For persons with EHS and associated multisystem tissue damage, the rate of recovery is highly individualized, ranging up to more than 1 year.\textsuperscript{65,119–125} However, evidence indicates that the degree of morbidity is negatively associated with proper recognition and treatment.\textsuperscript{69} If EHS is quickly recognized and immediately treated, morbidity and mortality are significantly decreased.

A patient who experiences EHS may have compromised heat tolerance and heat acclimatization even after physician clearance. Additional heat stress may reduce the patient’s ability to train and compete due to impaired cardiovascular and thermoregulatory responses.\textsuperscript{55,67} After recovery from EHS, an athlete’s physical activity should be restricted and the gradual return to sport individualized by a physician. The patient should be monitored daily by the clinician during exercise. During the return to exercise, the patient may experience some detraining and deconditioning not directly related to the EHS. He or she should be evaluated over time to determine if there has been complete recovery of exercise and heat tolerance.

Certified athletic trainers and other allied health care providers must be able to differentiate EAMCs, heat syncope, heat exhaustion, exertional heat injury, and EHS in order to treat these conditions appropriately in athletes. This position statement outlines the NATA’s current recommendations to reduce the incidence, improve the recognition, and optimize the treatment of these heat illnesses in athletes. Education and increased awareness will help to reduce both the frequency and severity of heat illnesses in athletes.
